Abstract: BACKGROUND: Persons infected with human immunodeficiency virus (HIV) have increased rates of coronary artery disease (CAD). The relative contribution of genetic background, HIV-related factors, antiretroviral medications, and traditional risk factors to CAD has not been fully evaluated in the setting of HIV infection. METHODS: In the general population, 23 common single-nucleotide polymorphisms (SNPs) were shown to be associated with CAD through genome-wide association analysis. Using the Metabochip, we genotyped 1875 HIV-positive, white individuals enrolled in 24 HIV observational studies, including 571 participants with a first CAD event during the 9-year study period and 1304 controls matched on sex and cohort. RESULTS: A genetic risk score built from 23 CAD-associated SNPs contributed significantly to CAD ($P = 2.9 \times 10^{-4}$). In the final multivariable model, participants with an unfavorable genetic background (top genetic score quartile) had a CAD odds ratio (OR) of 1.47 (95% confidence interval [CI], 1.05-2.04). This effect was similar to hypertension (OR = 1.36; 95% CI, 1.06-1.73), hypercholesterolemia (OR = 1.51; 95% CI, 1.16-1.96), diabetes (OR = 1.66; 95% CI, 1.10-2.49), 1 year lopinavir exposure (OR = 1.36; 95% CI, 1.06-1.73), and current abacavir treatment (OR = 1.56; 95% CI, 1.17-2.07). The effect of the genetic risk score was additive to the effect of nongenetic CAD risk factors, and did not change after adjustment for family history of CAD. CONCLUSIONS: In the setting of HIV infection, the effect of an unfavorable genetic background was similar to traditional CAD risk factors and certain adverse antiretroviral exposures. Genetic testing may provide prognostic information complementary to family history of CAD.

[†]The Myocardial infarction, Assessment of Antiretroviral and Genetic Factors in Human Immunodeficiency virus Infection Consortium

[‡]International Network for Strategic Initiatives in Global HIV Trials

Key points: We show in HIV+ persons that the CAD effect of an unfavorable genetic background is comparable to previous studies in the general population, and comparable in size to traditional risk factors and antiretroviral regimens known to increase cardiovascular risk.

Abstract

Background: HIV-positive persons have increased rates of coronary artery disease (CAD). The relative contribution of genetic background, HIV-related factors, antiretroviral medications, and traditional risk factors to CAD has not been fully evaluated in the setting of HIV infection.

Methods. In the general population, 23 common single nucleotide polymorphisms (SNPs) were shown to be associated with CAD through genome-wide association analysis. Using the metabochip, we genotyped 1875 HIV-positive, white individuals enrolled in 24 HIV observational studies, including 571 participants with a first CAD event during the 9-year study period and 1304 controls matched on gender and cohort.

Results: A genetic risk score built from 23 CAD-associated SNPs contributed significantly to CAD ($P=2.9 \times 10^{-4}$). In the final, multivariable model, participants with an unfavorable genetic background (top genetic score quartile) had a CAD odds ratio (OR) of 1.47 (95% confidence interval, 1.05-2.04). This effect was similar to hypertension (OR=1.36; 95% CI, 1.06-1.73), hypercholesterolemia (OR=1.51; 95% CI, 1.16-1.96), diabetes (OR=1.66; 95% CI, 1.10-2.49), >1 year lopinavir exposure (OR=1.36; 95% CI, 1.06-1.73) and current abacavir treatment (OR=1.56; 95% CI, 1.17-2.07). The effect of the genetic risk score was additive to the effect of non-genetic CAD risk factors, and did not change after adjustment for family history.

Conclusions: In the setting of HIV infection, the effect of an unfavorable genetic background was similar to traditional CAD risk factors and certain adverse antiretroviral exposures. Genetic testing may provide prognostic information complementary to family history of CAD.

Introduction:

A major long-term concern in HIV-positive persons includes increased rates and premature onset of coronary artery disease (CAD), stroke, and peripheral vascular disease, compared to the general population[1-6]. The pathogenesis of CAD in HIV is incompletely understood; a high prevalence of smoking, pro-inflammatory and pro-coagulant mechanisms in the context of immunosuppression[7-9], adverse viral effects on endothelial and other cells, and deleterious metabolic effects such as dyslipidemia and insulin resistance after exposure to certain antiretroviral treatments have been implicated[2, 10-12].

CAD has a strong hereditary component[13, 14]. Genome-wide association studies (GWAS) have identified common genetic variants that contribute to the risk of CAD in the general population [15, 16]. The Myocardial infarction, Assessment of Antiretroviral and Genetic Factors in Human Immunodeficiency virus Infection (MAGNIFICENT) Consortium was established with the aim of assessing the relative contribution of traditional risk factors, HIV-related factors, antiretroviral regimen, and genetic background to CAD in HIV-positive persons. We report here on 571 white HIV+ persons who experienced a first CAD event and 1,304 HIV+ matched controls without CAD events in 24 HIV observational studies. This represents the most comprehensive genetics-CAD study undertaken in HIV-positive persons.

Methods:

Study population, inclusion criteria. The MAGNIFICENT consortium includes 24 HIV observational studies from Europe, the US, Australia and Argentina (**supplementary material**). Participants gave written informed consent for genetic testing. The ethics committee of each study center approved the study. Applying a case-control design, we defined cases as HIV+, with a first CAD event during the study period (4.1.2000-3.31.2009). Controls were HIV+ and event-free during the study

period. For each case, we aimed to select 3 controls from the same cohort using risk-set sampling[17]. Controls were matched only on gender, to allow analysis of the effect of relevant non-genetic factors. Participants with cardiovascular events prior to the study period were excluded. Because most previous CAD GWAS in the general population were conducted in populations of European descent[16], the present report is restricted to participants of European descent.

CAD events. CAD events were validated by the treating physician and defined according to the Data Collection on Adverse events of Anti-HIV Drugs (D:A:D) study and the MONICA Project of the World Health Organisation[2, 18]. CAD events included definite myocardial infarction (MI); possible MI or unstable angina; percutaneous coronary intervention including coronary angioplasty and stenting; coronary artery bypass surgery; and fatal CAD, which required evidence of CAD before death. All CAD events in participating cohorts that occurred during the study period were included.

Power calculation, genotyping, quality control. We interrogated 23 single nucleotide polymorphisms (SNPs) with known CAD association in GWAS meta-analysis in the general population[16]. Using the ESPRESSO-CC Power Calculator[19], with projected 600 cases and 1800 controls, the study had an 80% power to capture the effect of SNPs with minor allele frequency (MAF) >0.1 and CAD odds ratio >1.25. Genotyping was performed on the Metabochip (Illumina, Eindhoven, Netherlands and Broad Institute, Harvard University/Massachusetts Institute of Technology), a custom array of 196,725 SNPs from gene regions associated with multiple metabolic/cardiovascular traits in GWAS [20]. The Metabochip was developed by leader groups in the field to facilitate affordable genotyping of; i) recognized SNPs; ii) the genetic regions that carried them, with the goal of discovering causal variants associated with the recognized tag SNPs. However, the study was not designed or powered for a Metabochip-wide association study, which would require a significance threshold of $P < 2.5 \times 10^{-7}$, i.e. $P = 0.05$ divided by the number of SNPs interrogated [196,725]).

Participants were filtered based on gender check (heterozygosity testing), and cryptic relatedness. We used a modified Eigenstrat approach to identify and exclude population outliers and to control for the possibility of spurious associations resulting from residual population stratification[21]. This method derives the principal components of the correlations among common (MAF>5%) gene variants, which reflect population ancestry, and corrects for those correlations in the subsequent association tests by integrating the coordinates of the significant principal component axes as covariates (Eigenstrat covariates) in the models.

Non-genetic CAD risk factors. Covariates were selected *a priori* based on published CAD effect and included in the final model regardless of statistical significance: High total cholesterol (>6.2 mmol/L[22] or being on lipid-lowering medication), low HDL-cholesterol (<1.04 mmol/L)[22], diabetes mellitus (confirmed plasma glucose >7.0 mmol/L [fasting] or >11.1 mmol/L [nonfasting] or taking antidiabetic medication)[23, 24], hypertension (systolic \geq 140 mmHg or diastolic \geq 90 mmHg or taking antihypertensive medication), smoking (never, past or current), family history of CAD, age (per 5-year increments[25]). HIV-related covariates were defined *a priori*, based on their contribution to CAD in the D:A:D study[25]: CD4+ count and HIV RNA value (closest to the event date), current ART exposure, current abacavir exposure, and cumulative exposure to lopinavir and indinavir. Because few patients had >2 years exposure and the CAD effect of 1-year and >2 years of treatment was equivalent, these drug exposures were considered as binary covariates, i.e. < or >1 year.

Missing data. Certain covariates were unavailable or had >20% missing data (**Supplementary Table 3**). Mostly, these data were systematically missing in entire cohorts, and therefore assumed to be missing at random. This assumption was further checked by comparing summary statistics on non-missing values across cohorts. There was no evidence that cohorts differed significantly in the distribution of important confounders. Therefore, single imputation using predictive mean matching was performed to replace missing data for glucose, total and HDL-cholesterol, blood pressure, smoking, family history,

duration of lopinavir and indinavir exposure, HIV RNA, and CD4+ count. Missing values were imputed using models with the predictors age, sex, abacavir at time of event, region, and case/control status[26]. Primary analyses utilized the imputed dataset; sensitivity analyses utilized the non-imputed dataset (**Supplementary Figures 1B and 3**).

Genetic association analyses. We built two *a priori* defined genetic risk scores using 23 SNPs (or a proxy with $r^2 > 0.8$) with known CAD association[16] (**Supplementary table 2**); i) additive genetic score (number of CAD risk alleles; heterozygous=1, homozygous=2; i.e. scores ranged from 0 to 46; higher scores indicate a higher CAD risk); ii) additive weighted genetic score that takes into account the effect size reported in the reference paper[16]. For a SNP with, e.g., a CAD odds ratio of 1.2: reference allele=0, heterozygous=0.2, homozygous risk allele=0.4. The numbers obtained for each of the 23 SNPs were added to create an individual weighted genetic risk score.

Statistical analysis. First, we tested the associations of non-genetic factors using a conditional logistic regression model[27]. Then, we tested the weighted genetic score plus the 5 Eigenstrat covariates and added them to the model, by dividing study participants into 4 genetic score quartiles. We made a *post-hoc* test for an interaction between genetic score and traditional risk factors plus factors that contributed to CAD in the D:A:D study[25]. The pseudo- r^2 from each conditional logistic regression model was used as an estimate of the percentage of explained CAD variability in the study population. Analyses were done using PLINK, R, SAS v9.2 (SAS Corporation, Cary, NC) and Stata v12.0 (StataCorp LP, College Station, TX).

Sensitivity analyses. To assess the robustness of results, we repeated the final model in participants with; i) complete (non-imputed) data for all covariates; ii) stringent case definition (definite MI, coronary artery bypass surgery and fatal CAD, plus corresponding controls); iii) definite MI plus corresponding controls; iv) family history excluded from the model.

Exploratory genetic association analyses. First, all 196,725 SNPs present on the Metabochip were separately tested for association with CAD by conditional logistic regression. Second, to search for additional, weaker genetic associations in the regions containing known CAD-associated genes or variants, we considered as a group all SNPs located in/near (\pm 5kb) the 23 CAD-associated genes[16] and as a separate group the SNPs mapping to genes associated with traits indirectly related to CAD (total, LDL-, HDL-cholesterol, diabetes mellitus, fasting glucose, body mass index[20]). The distribution of association p-values was compared between these groups and all other SNPs genotyped on the Metabochip using the two-sample Kolmogorov-Smirnov test. Third, we evaluated a potential association of CAD events with mitochondrial DNA (mtDNA) haplogroups.

Results:

Study population. We received DNA specimens from 702 cases and 1,849 controls. Twenty-one cases and 158 controls were excluded because of registration in the cohort of the control after the event date of their matched case ($n=124$), insufficient DNA quantity or quality ($n=42$), sample administrative error ($n=7$), non-white self-reported origin ($n=4$), event occurred after study ended ($n=1$), missing genetic consent ($n=1$). After genotyping quality control, 97 cases were excluded because they were population outliers in the Eigenstrat analysis ($n=89$) or genetically related with another participant ($n=8$); corresponding controls were also excluded. The final study population included 1,875 participants (571 cases and 1,304 controls).

Among the 571 cases, there were 273 definite MI, 48 possible MI or unstable angina, 179 percutaneous coronary interventions, 32 coronary artery bypass surgeries and 39 fatal CAD. Characteristics of participants are shown in **Table 1**. The median age at first CAD event was 50 years.

Cases were older than controls, and more likely to be smokers, have elevated cholesterol and glucose levels, a family history, and treatment with abacavir.

Non-genetic factors contributing to CAD. All covariates were significantly associated with the odds ratio of a first CAD event, except low HDL-cholesterol ($p=0.29$), being on ART at time of CAD event ($p=0.12$), CD4+ count ($p=0.44$), and HIV viremia ($p=0.88$) (**Figure 2**). In the complete case analysis (participants without missing covariate data), the sample size was 720 individuals (183 cases, 537 controls). For the imputed models, the sample size was 1,875 (571 cases, 1304 controls). Conditional logistic regression models for the imputed dataset were consistent with the complete case analysis as regards direction and effect size of individual covariates (**Supplementary Figures 1B and 3**). Therefore, the final model and the results presented hereafter are based on the imputed dataset.

CAD odds ratio according to genetic risk score. In unadjusted analysis (**Table 2**), participants in the 3rd and 4th genetic risk score quartiles had an increased CAD odds ratio (OR), compared to the 1st quartile (OR=1.34; 95% confidence interval [CI], 1-1.79, $p=0.05$; and OR=1.59 [95% CI, 1.19-2.13], $p<0.01$, respectively). In the final, multivariable model, the additive and the weighted genetic score were associated with the CAD odds ($P=1.3 \times 10^{-4}$ and $P=2.9 \times 10^{-4}$, respectively). Cases were more likely to be in the upper 2 genetic score quartiles compared to controls ($p=0.01$; **Supplementary Figure 2**). The effect of the weighted genetic score (CAD OR=1.47 for the 4th quartile, compared to 1st quartile; 95% confidence interval [CI], 1.06-2.04; $p=0.02$) was similar to the effect of established CAD risk factors and certain antiretroviral medications (**Figure 2 and Supplementary Table 1A**). This included family history (OR=2.05; 95% CI, 1.54-2.74), hypertension (OR=1.36; 95% CI, 1.06-1.73), hypercholesterolemia (OR=1.51; 95% CI, 1.16-1.96), diabetes (OR=1.66; 95% CI, 1.10-2.49), current smoking (OR=2.48; 95% CI, 1.85-3.32), >1 year lopinavir exposure (OR=1.36; 95% CI, 1.06-1.73) and current abacavir treatment

(OR=1.56; 95% CI, 1.17-2.07). An unfavorable genetic background had an additive effect on the CAD odds, without a significant interaction effect ($p=0.60$; **Figure 3 and Supplementary Table 1B**).

Relative contribution of clinical, HIV-related and genetic factors. In the final model, 7.5% of the CAD odds ratio variability was explained by age, 3.1% by current smoking, 1.9% by family history, and 0.9% by genetic score. Smaller percentages were explained by traditional and HIV-related risk factors, e.g., 0.7% each by hypercholesterolemia, >1 year lopinavir or current abacavir treatment; 0.5% each by diabetes or hypertension (**Figure 4**). Addition of the genetic score to the clinical model improved the fit of the model ($\chi^2=6.28$, $p=0.01$).

Sensitivity analyses. Models restricted to participants with non-imputed data, stringent case definition (344 cases, 806 corresponding controls), and definite MIs (273 cases, 651 corresponding controls) showed similar results, except for a widening of confidence intervals due to reduced sample size (**Supplementary Figure 3 and 4 and 5**). Removing family history did not change the estimates for the genetic score (**Table 2, Supplementary Figure 6**).

Exploratory metabochip-wide analyses, mtDNA variants. None of the 196,725 SNPs on the array were associated with CAD events in a metabochip-wide analysis after correction for multiple testing (**Supplementary Figure 7**). The global distribution of association p-values was not significantly different between the 5,070 SNPs within CAD-associated genes, the 36,863 SNPs within genes with a potential indirect CAD association[16], and the rest of the SNPs on the Metabochip, indicating an absence of enrichment of potentially interesting association signals in the first two groups. mtDNA coverage of the Metabochip was found to be unreliable, with an excess of seemingly polymorphic (heteroplasmic) mtDNA SNPs; 80% of the participants displayed >1 heteroplasmic SNP out of 135 SNPs mapped to mtDNA (total, 5604 heteroplasmic calls; **Supplementary results, supplementary figure 8**). Results were also inconsistent with the complete mtDNA genomes of two participants that had been previously Sanger sequenced [28], with 47% unmatched SNPs (64/135 positions, **Supplementary Table 4**).

Discussion:

This is the first large scale analysis of clinical, HIV-related and genetic risk factors that contribute to CAD in HIV-positive persons. Our findings suggest that the effect of an unfavorable genetic background on CAD events is comparable to well-established traditional risk factors and certain antiretroviral regimens. The genetic risk score, which was defined *a priori* and captures the joint effect of 23 common SNPs with known CAD association in the general population[16], remained independently associated with CAD after considering multiple non-genetic factors and in sensitivity analyses, suggesting that the effect is robust.

In this HIV+ study population, genetic background explained a larger proportion of the CAD variability than did diabetes, hypertension or dyslipidemia, but a smaller proportion than age or current smoking. Our exploratory analyses using the metabochip did not provide any novel insight about the genetics of CAD in HIV+ persons. This was expected, since the study was designed to assess a panel of candidate SNPs with validated CAD association and was not powered for metabochip-wide discovery of novel gene variants.

Family history and genetic risk score contributed to CAD to a similar degree and the effect of the genetic score did not change after adjusting for family history. This suggests that family history, which may reflect genetic background, but also environmental, social and lifestyle factors shared among family members[29, 30], and assessment of common genetic variants capture independent, complementary effects on CAD in HIV-positive persons. This is consistent with the results by Ripatti and colleagues, a large study in the general population that assessed a similar genetic score [31].

An unfavorable genetic background had an effect on CAD comparable to certain antiretroviral agents known to increase cardiovascular risk. Because the magnitude of the CAD effect of certain drugs (e.g. abacavir) is unresolved[32], we based selection of drug exposure covariates on the D:A:D study, the

largest ongoing consortium of observational HIV studies[2, 25]. The increased CAD risk associated with lopinavir and indinavir is consistent with their previously recorded metabolic effects[2, 33]. Low CD4+ count or detectable HIV viremia at the time of the CAD event were not associated with CAD in our dataset, consistent with the D:A:D study[34]. Other authors have noted adverse effects of immunosuppression on CAD risk[35, 36].

Strengths of this study include the assembly of a large study population of HIV-positive persons who experienced a first CAD event during a 9-year study period; rigorous quality control of the genotyping data; exclusion of population outliers and correction for residual population stratification; physician validation of all CAD events; analysis of only SNPs and non-genetic covariates with established CAD association; and robust results in sensitivity analyses. Our study was limited by the effort required to establish the MAGNIFICENT consortium. Even though HIV+ populations are aging[37], the number of HIV-positive persons who have experienced CAD events is limited and not all studies include consent for genetic testing. Because demonstration of the CAD effect of 13 of the 23 SNPs required meta-analysis of >86,000 participants from multiple GWAS in the general population[16], additional CAD-associated SNPs with modest effect sizes may emerge from HIV+ study populations larger than the MAGNIFICENT consortium. At the time of study design, GWAS-based CAD associations were essentially limited to white populations, so we restricted the present analysis to white participants; our findings may not be applicable to other populations.

Our findings suggest that genetic testing may provide prognostic information complementary to that afforded by family history, traditional risk factors, and antiretroviral regimen. Particularly in high risk patients, knowledge of a deleterious genetic CAD predisposition might further emphasize the rationale for aggressive risk factor modification and selection of a CAD-neutral antiretroviral regimen to achieve HIV control. The clinical value of genetic testing will rely on demonstration of improved CAD risk stratification in prospective studies, as shown by Ripatti in the general population[31, 38]. This was

beyond the scope of the case-control design of our consortium. Areas for future investigation include addition of genetic score to, e.g. Framingham or D:A:D score in prospective HIV study settings; comparison of genetic CAD prediction in HIV-positive vs. HIV-negative populations; and integration of genetic background and plasma biomarkers of inflammation, coagulation and endothelial function to predict CAD in HIV[7, 39].

Funding:

This work was supported by the Swiss National Science Foundation (SNF; project 324730_127631/1), the Swiss HIV Cohort Study [SNF grant 33CS30_134277, SHCS project 599], an INFECTIGEN grant from the Universities of Geneva and Lausanne [to P.E.T.], the Intramural Research Program of the National Institute of Allergy and Infectious Diseases, and unrestricted grants from Gilead Sciences and Merck Sharp and Dohme Switzerland to the SHCS research foundation. The IdiPAZ Biobank is supported by Instituto de Salud Carlos III, Spanish Health Ministry (retic RD09/0076/00073) and Farmaindustria, through the Cooperation Program in Clinical and Translational Research of the Community of Madrid. Red de Investigación en SIDA grant [ISCIII-RETIC RD06/0006/1017, ISCIII-MA06/0164].

Acknowledgments:

The authors acknowledge the contributions of the different research institutions, the effort and commitment of investigators, study nurses, laboratory personnel, and participants. We thank the Cardio-Metabochip Consortium for designing the Metabochip and making it available at a competitive price. We thank the participants of the IdiPAZ Biobank integrated in the Spanish Hospital Biobanks Network for clinical samples.

The authors report the following potential conflicts of interest, none of which pertain to this work:

A.B.W. currently is Manager Scientific Affairs with the Crucell Vaccine Institute; the present work was initiated while she was working full-time at the Academic Medical Center (AMC) at University of Amsterdam and has been completed through her continued affiliation with the AMC. H.F.G. has been adviser and/or consultant for GlaxoSmithKline, Abbott, Gilead, Novartis, Boehringer Ingelheim, Roche, Tibotec, Pfizer and BMS, and his institution has received funding from Roche, Abbott, BMS, Gilead, Astra-Zeneca, GlaxoSmithKline, and MSD. C.T. has received lecture fees from Viiv and travel expenses from Viiv, Gilead. L.J. has been a consultant for BMS. E.M. has received consultancy and lecture fees from Abbott, BI, BMS, Gilead, GSK, MSD, Theratechnologies, Tibotec, and ViiV. J.R. has received advisory/lecture/consulting fees from Abbott, Bionor, BI, BMS, Gilead, GSK, Merck, Novartis, Janssen, GSK, Pfizer, Vertex and ViiV and his institution has received funding from Abbott, MSD, Roche. J.-C.W. has received advisory/lecture fees from Abbott, BMS, BI, Pfizer, Tibotec and travel fees from Gilead. S.D. has received advisory fees from BMS and his institution has received consultancy fees from Viiv and travel fees from Janssen, Viiv, Gilead, Abbvie and BMS. S.M. has received consulting/advisory fees from AbbVie, BI, BMS, Gilead, Janssen, Roche and travel grants from the same companies plus MSD. J.G. has received consulting fees and his institution has received funding from Gilead, Abbott, BMS, MSD, Janssen. The institution of C.B., K.P. and M.L. has received funding from BI, BMS, Gilead, GSK, Janssen, MSD, Pfizer, Roche. M.L. has received payments for serving on Data and Safety Monitoring Boards for Sirtex Pty Ltd. A.D. has received advisory/consultant fees from Janssen, ViiV, Abbott, and Gilead, received travel grants from ViiV and Abbott and funding from ViiV and Janssen. A.D. has received advisory fees from Gilead and Viiv, consulting fees from Janssen and Abbott, travel grants from Abbott and Viiv, and his institution has received funding from Viiv and Janssen. I.B. has received research funding, consulting/lecture fees from Abbott, Gilead, BMS, ViiV, Janssen. J.G.G. has received consultancy fees from Abbott, Janssen, MSD, BMS, Gilead, ViiV and Roche. J.R.A. has

received advisory/speaker fees and grant support from Viiv, Tibotec, Janssen, Abbott, BMS, Gilead, MSD. E.N. has received consultant fees from Gilead, BI, MSD, Abbott, Tibotec, GSK, BMS. P.D. has received advisory, consultant and/or lecture fees and has been DSMB member for Gilead, Abbott, Janssen, BI, BMS, MSD, Theratechnologies, ViiV, Ferrer. G.F. has received consultancy/lecture fees and funding from AbbVie, Janssen, Gilead, BMS, MSD, Pfizer, Roche, ViiV. A.M. currently is Medical Director, HIV/Endocrinology with EMD Serono; the present work was initiated while she was working full-time at Tufts University and has been completed through her continued affiliation with Tufts. R.W.'s institution has received travel grants from Travel grants from Abbott, Bi, BMS, Gilead, GSK, MSD, Pfizer, Roche, TRB Chemedica and Tibotec. P.R. has been adviser for GSK, Gilead, and Janssen, and his institution has received funding and/or travel support from Gilead, ViiV, MSD, Janssen, BMS, and BI. He has served on DSMB and endpoint adjudication committees for Janssen, and his institution has received honoraria for development of educational presentations from Gilead. H.C.B.'s institution has received travel grants, honoraria and unrestricted research grants from GSK, BMS, Gilead, Janssen, Roche, Abbott, Tibotec, BI and ViiV and is supported by unrestricted grants from Santésuisse and the Gottfried and Julia Bangerter-Rhyner-Foundation. P.E.T. has received advisory fees from Janssen, consultancy fees from Gilead, honoraria from Viiv, and his institution has received advisory fees from Gilead, MSD, honoraria from Viiv, and travel expenses from MSD and Viiv. All other authors: No conflicts of interest.

Table 1: Characteristics of the cases and controls at the matching date.

	Cases	Controls
Total	571	1304
Male gender* (%)	91.1	91.3
Age (years), median (range)	50.0 (22-85.5)	45.0 (16.5-81.3)
Smoking (%)		
Never	22.8	31.4
Past	23.3	21.6
Current	53.9	46.9
Hypercholesterolemia (%)	45.5	31.8
Low HDL-cholesterol (%)	43.1	39.3
Diabetes mellitus (%)	19.4	13.6
Arterial hypertension (%)	43.6	31.1
Family history of coronary artery disease (%)	25.7	15.4
Receiving antiretroviral therapy (%)	87.7	79.3
Currently on abacavir (%)	25.6	17.6
Duration of treatment with indinavir (years), median (range)	0 (0-8.2)	0 (0-11.3)
Duration of treatment with lopinavir (years), median (range)	0 (0-8.0)	0 (0-8.7)
CD4+ T-cell count (cells/ μ L), median (range)	497 (11-1688)	500 (10-1905)
HIV RNA (log copies/mL), median (range)	3.8 (0 -14.6)	3.9 (0-13.6)
HIV RNA		

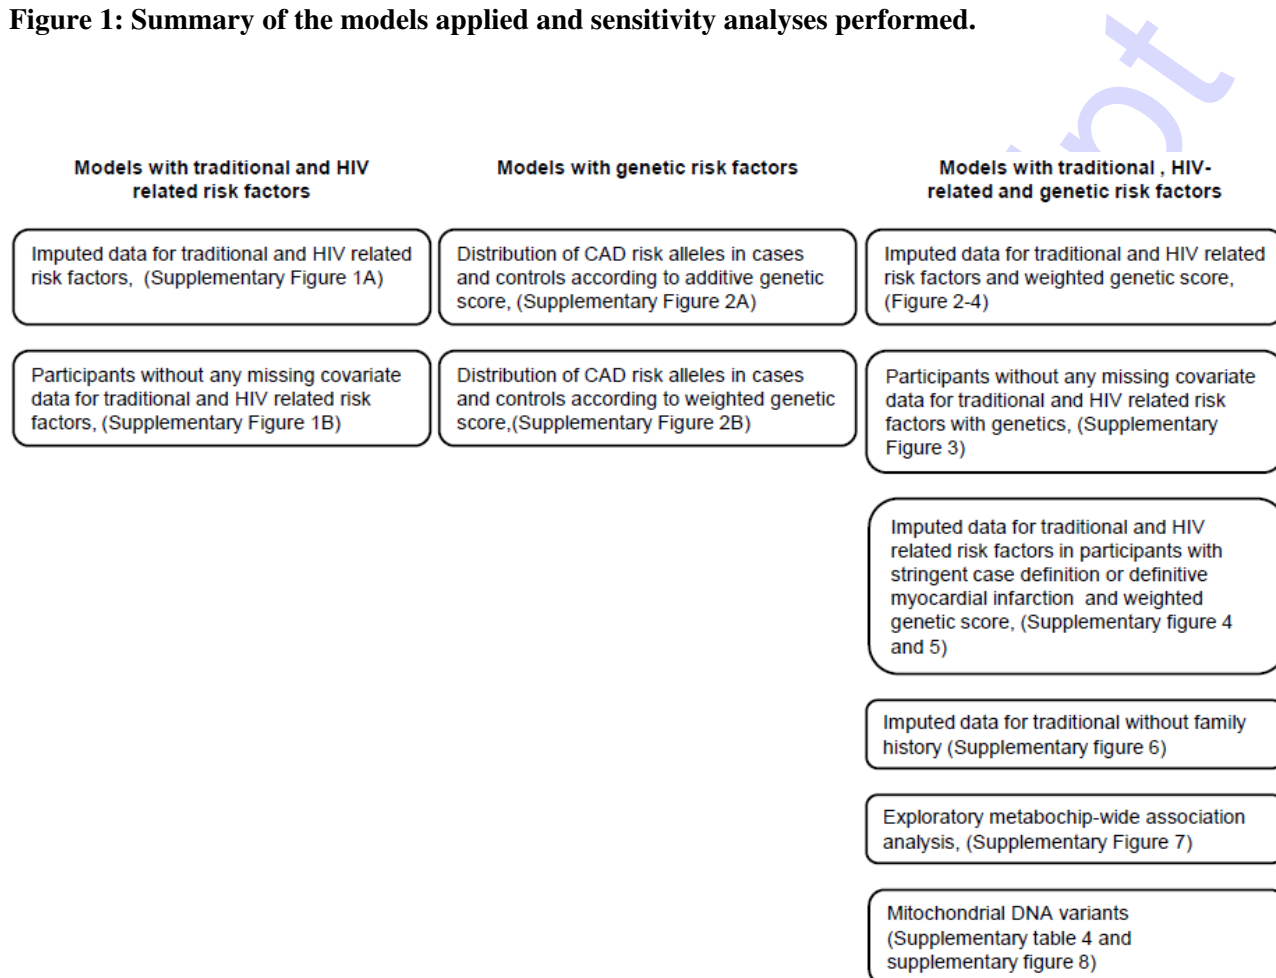

<50 copies/mL (%)	63.2	60.2
<400 copies/mL (%)	74.1	68.2

Note. *Cases and controls were matched on gender and cohort.

Table 2. Odds ratio for CAD according to weighted genetic risk score quartile

	Genetic risk score and 5 Eigenstrat covariates, unadjusted for non-genetic covariates	Final model, with family history of CAD (Fig. 2)	Final model, without family history of CAD (Supp. Fig. 7)
Genetic risk score quartile 2 vs. quartile 1	1.27 (95% confidence interval [CI], 0.95-1.69); p=0.11	1.03 (95% CI, 0.74-1.44); p=0.84	1.04 (95% CI, 0.75-1.44); p=0.82
Genetic risk score quartile 3 vs. quartile 1	1.34 (95% CI, 1-1.79); p=0.05	1.25 (95% CI, 0.90-1.74); p=0.18	1.25 (95% CI, 0.90-1.72); p=0.18
Genetic risk score quartile 4 vs. quartile 1	1.59 (95% CI, 1.19-2.13); p<0.01	1.47 (95% CI, 1.06-2.04); p=0.02	1.47 (95% CI, 1.06-2.03); p=0.02

Figure 1: Summary of the models applied and sensitivity analyses performed.

Edward McKone

Figure 2: Contribution of traditional CAD risk factors, HIV-related factors and weighted genetic score to CAD risk in multivariable analysis

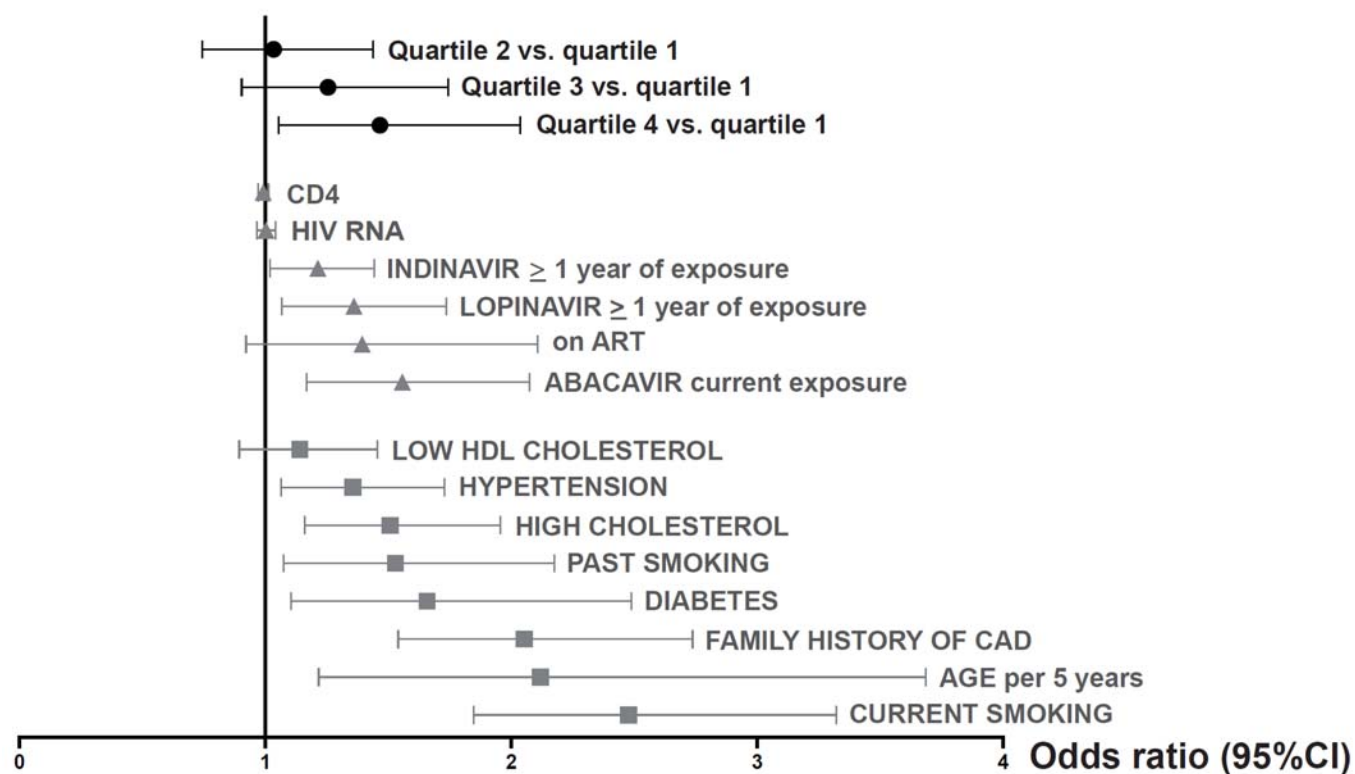

Figure 3: CAD risk according to genetic score quartile and number of non-genetic CAD risk factors
(odds ratio and 95% confidence interval).

Figure 4: CAD variability explained by traditional risk factors, HIV-related factors and genetic background.

Figure Legends

Figure 1. [Figure 1 has no legend]

Figure 2. Results are represented as the estimated effect and 95% confidence interval on the odds ratio of a first CAD event for genetic risk score quartile (*black dots*), HIV-related variables (*gray triangles*), and traditional CAD risk factors (*gray squares*). Results for the final, fully adjusted model (see Supplementary Table 1A) and for the weighted genetic risk score (see Methods section) are shown.

Figure 3. Participants are stratified into 12 groups by weighted genetic score quartile (quartile 1, 2, 3, and 4) and by the number of non-genetic risk factors (0-2, 3-4 or more than 4 non-genetic CAD risk factors). The first group is the reference group (odds ratio=1), i.e. participants with 0-2 non-genetic risk factors who are in genetic risk score quartile 1. The sum of all non-genetic CAD risk factors is considered (presence of risk factor=1, absence of risk factor=0), including traditional risk factors and additional factors that contributed significantly to CAD risk in the D:A:D study [25], i.e. age, past smoking, exposure >1 year to lopinavir, exposure >1 year to indinavir, current exposure to abacavir. Q, quartile.

Figure 4. Variability in the CAD odds ratio explained by the final model: 21.1%. Of this, age: 7.5%, current smoking: 3.1%, past smoking: 0.4%, high total cholesterol: 0.7%, hypertension: 0.5%, diabetes: 0.5%, low HDL-cholesterol: 0.1%, family history of CAD: 1.9%, genetic risk score: 0.9%, current ART: 0.2%, current abacavir: 0.7%, lopinavir (>1 year): 0.7%, indinavir (>1 year): 0.3%, HIV viral load: 0%, CD4+ count: 0%. LPV, lopinavir. IDV, indinavir.
